ARTICLE INFO	A B S T R A C T
Keywords: Electropolishing Inhibitors Amines Steel	Electropolishing of Steel in phosphoric acid is considered as corrosion rate of Steel and due to the economic importance of Steel, there are several researches deals with acceleration and inhibition of this process. This paper threw some light on the effect of adding some organic amines on the electropolishing of steel. Different concentration were used from 10^{-5} mol.L ⁻¹ to 10^{-2} mol.I ⁻¹ and different organic amines derivatives (methyl amine, dimethyl amine, diethyl amine, triethyl amine, diethanol amine and triethanol amine) were used. Electropolishing process of steel inhibited by different ratio. The results show that organic amines have strongest inhibiting effect ranging from 5% to 59.7% and the thermodynamic parameters as ΔS^* , ΔH^* and ΔG^* were studied. The values of ΔG_{ads} are given in negative values in all cases means that spontaneous adsorption of inhibitor on steel surface and strong interaction between the inhibitor molecules and metal surface. It lies in the range of (32–38) kJmol ⁻¹ for Flory - Huggins and (15–17) KJ mol ⁻¹ for kinetic isotherm. It's found that (ΔG_{ads}) values are more positive than -40 Kjmol ⁻¹ indicating that the inhibitors are physically adsorbed on the metal surface and the adsorption isotherm were given. The effect of amines compounds with nitrogen free, on the

1. Introduction

Electropolishing is widely employed in industry for micro finishing and debarring of different metallic components. A large number of electrolytic baths with different operating conditions are reported in the literature [1–4] but there is little information available on the mechanisms involved in Electropolishing in these systems. Most of the published work related to fundamental understanding of Electropolishing involved the study of Electropolishing of copper in phosphoric acid [5–12] although some work on steel, nickel, and chromium have also been reported [13–17]. In most of these studies electropolishing has been related to the existence of transport limited current plateau in the anodic polarization curve.

The corrosion of Steel and its alloy is of industrial concern that has received a considerable amount of attention. The corrosion of steel in acid media is important in the context of pickling, acid cleaning, etc. because of the general aggressiveness of acid solutions, the use of inhibitors to control the destructive attack of acid environment finds widespread application in many industries. A variety of organic compounds with functional groups containing heteroatom which can donate electron pairs are found to be useful as inhibitors in various media

[18].

Phosphoric acid H_3PO_4 is widely used in the protection of fertilizers and surface treatment of steel such as chemical and electrolytic polishing or etching, removal of oxide film, phosphating, passivating, and surface cleaning [19]. However, little work appears to have been done on the corrosion inhibition of steel in H_3PO_4 . Hence,

corrosion process is revealed by adsorption curves. The efficiency in inhibition decreases in the order: triethanol amine > diethanol amine > triethyl amine > diethyl amine > diethyl amine > methyl amine.

The aim of this work is to examine the corrosion behavior of steel in $\rm H_3PO_4$ in the presence of low price, low toxicity and easy production surfactants.

The aim of this study is the analysis of the effect of some amine derivatives for the inhibition of steel corrosion in $8 \text{ M} \text{ H}_3\text{PO}_4$ at different conditions. The rate of steel corrosion is determined by measuring the anodic limiting current.

2.2. Apparatus and procedure

Fig. 1. Represents the components of the cell and the electrical circuit that has been used in this work. The cell is made of a rectangular plastic container with dimensions $(5.1 \times 5.0 \times 10.0 \text{ cm})$ with electrodes fitting the whole section. Two electrodes, each as rectangular steel plate of 10 cm height and 5 cm width, are located 5.1 cm apart. A porous poly vinyl chloride diagram is used to prevent the effect of H₂ bubble.

The electrical circuit used in this work consists of 6 V D.C. power supply of 6 V with a voltage regulator and multi-range ammeter is connected in series with cell. Potential differences are obtained by increasing the cell current stepwise and measuring the steady state anode potential against a reference electrode consist of a Steel wire immersed in a cup of Luggin probe filling with solution at concentration similar to that in the cell, the tip of Luggin probe is placed 0.5–1 mm tube from the anode surface.

The Potential difference between the anode and the reference electrode is measured by high impedance potentiometer. Ortho-phosphoric acid concentration is prepared from Analar ortho-phosphoric acid and distilled water. The anode height is 2 cm. before each run the block part of the anode is insulated with poly-styrene lacquers and the active surface of the anode is polished with fine emery paper, degreased with trichloroethylene, Washed with alcohols and finally rinsed in distilled water. Electrode treatment is similar to that used by Wilke [20]. The rate of Steel corrosion under different conditions is determined by measuring the limiting Current at 25 °C. Six different concentration of organic amines with 8 M H_3PO_4 .

3. Results and discussions

3.1. Leveling process

The principle in electro-polishing is called leveling [21–23]. It can be explained by mass transfer mechanism [21]. A cell with a diaphragm has been used in this study. The use of this cell eliminates the effect of the evolved hydrogen gas at the cathode from affecting the rate of mass transfer at the anode, that is, natural of mass by convection. A cell

without diaphragm is used to study the effect of hydrogen gas evolved
at the cathode on the rate of mass transfer at the anode, i.e., forced
convection. The study of leveling is based on the classical current vol-
tage curves of electro-polishing (as shown in Fig. 2). A typical polaro-
gram is obtained in this study for triethanol amine in both cases of
divided and undivided cell. The curve is divided into three stages: A)
The first stage, the current density(c.d) is proportional to the voltage. B)
The second stage of the curve, the metal undergoes electro-polishing. In
the first stage, etching takes place as well as in last part, some localized
pitting occurs [22].

3.2. Effect of Amine concentration on the limiting current

The observed limiting current, which represents the rate of Steel metal anodic corrosion in phosphoric acid at different temperature, are found that, the limiting current decrease with increasing the concentration of organic amines. Fig. 3 shows the dependence of limiting current on the bulk concentration in absence and in presence of organic amines. It has been found that, the limiting current decreases with increasing the concentration of organic amines. From the practical point of view, we can recommend on the basis of results that, it may use in this range of concentration to inhibit the corrosion of steel in 8 M $\rm H_3PO_4$ acid in all types of amines to be used in this work

When the limiting current in absence of amines (I_{blank}), and in the presence of organic amines ($I_{organic}$), the percentage of inhibition can be calculated from the following equation

Fig. 1. The electrolytic cell and the electrical circuit.

Fig. 2. The relation between the current and potential at different electrode height, in 8 M H₃PO₄, and the temp is 25 °C.

Fig. 3. The relation between limiting current and amines concentration at 25 °C.

Fig. 4. Relation between concentration and % of inhibition at 25 °C.

$$\%inhibition = \frac{I_{blank} - I_{organic}}{I_{blank}} \times 100$$
(2)

Fig. 4 and Table 1 show that, the percent inhibition caused by organic amines range from 5% to 59.9% depending on amine type and its concentration.

With increasing the concentration of amines the limiting current decreases and this agree with the finding of other authors whom worked within the same range of concentration using other anode geometries [24,25] The decreasing in the limiting current with increasing with amine concentration can be explained with the following reasons

- 1 The solubility of dissolved Ferrous phosphate in ortho phosphoric acid, which is responsible for the limiting current, decreases with increasing amine concentration
- 2 Increasing the viscosity of the solution with increasing amine concentration, with consequence decrease in the diffusivity of ${\rm Fe}^{+2}$

Table 1

according to Stokes-Einstein equation [26].

 $\eta D /T = constant$

(3)

Where: η is the Viscosity of the solution (g.cm⁻¹ s⁻¹).

D is the diffusion coefficient of Fe^{+2} (cm 2 s⁻¹), and T is the absolute temperature (K).

Also the increase in solution viscosity with increasing in phosphoric acid concentration results in an increase in the diffusion layer thickness which represent the resistance to the rate of mass transfer of Fe⁺² from anode surface to the bulk solution (Tables 2–5).

3.3. Adsorption isotherms

It is generally agreed that the adsorption isotherm of the inhibitor at the metal interface is the first main role of the mechanism of inhibitors action in aggressive acid media. Four types of adsorption may take place in the inhibition phenomena involving organic molecules at the metal-solution interface namely:

- a) Electrostatic attraction between charged molecules and metal.
- b) Interaction of lone pairs of electron in the molecules with the metal.
- c) Interaction of electrons with the metal.
- d) A combination of the above [27].

Chemisorptions involves sharing or charge transfer from the inhibitor molecule to the metal surface in order to form a coordinate bond, in fact, electron transfer is typical in transition metals having vacant low energy electron orbital.

Concerning inhibitors, electron transfer can be expected with compounds having relatively loosely bound electrons. This situation may arise because of the presence (in adsorbed inhibitor) of multiple bonds or aromatic rings of a Π character [28–35].

The inhibition efficiency of homologous series of organic substances, differ only in the heteroatom, is usually in the following sequence:

P > Se > S > N > O

Table 6

The values of K,X and 1/Y of amines according to Longmuir, Flory – Huggins, and Kinetic Adsorption Isotherm.

Compound	Flory – Huggins		Longmuir	Kinetic Adsor	ption Isotherm		
	x	K	К	K'	Y	1/Y	К

diethanol amine	15.16	36.04	16.95
Triethanol amine	14.22	38.15	17.50

The electrochemical processes on the metal surface are likely to be closely to the adsorption of the inhibitor which is known to depend on the structure of the inhibitor [36].

The Adsorption of the inhibitor molecules from aqueous solutions can be regarded as substitution adsorption process between the organic compound in the aqueous phase, (org._(aq.)) and the water molecules at the electrode surface, $(H_2O_{(s)})$.

$$Org_{(aq)} + xH_2O_{(s)} = Org_{(s)} + x (H_2O)$$
 (4)

Where X (the size ratio) is the number of water molecules displaced by one molecule of organic inhibitor.

Adsorption isotherms are very important in determining the mechanism of organo-electrochemical reactions. The most frequently used isotherms are those of Langmuir, Frumkin, Parsons, Temkin, Flory-Huggins, and Bockris-Swinkels [37]. These entire isotherms are of the general form:

$$f(\Theta, \mathbf{x}) \exp^{[-a\Theta]} = KC \tag{5}$$

where $f(\Theta,x)$ is the configuration factor depends essentially on the physical model and assumption underlying the derivation of the isotherm. The mechanism of inhibition is generally believed to be due to the formation and maintenance of a protective film on the metal surface [38].

$$\Theta = I - (I_I - I) \tag{6}$$

The degree of surface coverage (Θ)

Inhibitors adsorption characteristics can be estimated by using the Langmuir isotherm given by: [35]

$$KC = (\Theta/1) \cdot \Theta \tag{7}$$

Where K is the equilibrium constant of adsorption process, C is the concentration and Θ is surface coverage.

Inhibitors adsorption characteristics can be done using Langmuir isotherm

$$C/\Theta = C + 1/k \tag{8}$$

where K is the equilibrium constant of adsorption process, C is the inhibitor concentration in the bulk solution and Θ is the surface coverage. By plotting C/ Θ & C, it is found that Langmuir isotherm doesn't verified by those results.

This explains:

- i There is no interaction between adsorbed molecules
- ii The energy of adsorption is independent on the surface coverage
- iii The solid surface contains a fixed number of adsorption sites and each hole adsorbed species

Fig.5 and Tables 6 and 7 show the Flory-Huggins adsorption isotherm for copper electrode in H_3PO_4 solution, plotted as log Θ /C against log (1- Θ) at different temperatures. Straight lines are obtained with a slope X and intercept log x K. The experimental data fit the Flory-Huggins adsorption isotherm which is represented by:

$$\log \Theta/C = \log x k + x \log (1-\Theta)$$
(9)

where x is the number of water molecules replaced by one molecule of the inhibitor. The adsorption of inhibitors at metal-solution interface may be due to the formation of electrostatic or covalent bonding between the adsorbents and the metal surface. [39]

The kinetic thermodynamic isotherm may be written in the form [40] (Fig. 5)

$$\log(\Theta/1) \cdot \Theta = \log K' + y \log C \tag{10}$$

Where y is the number of inhibitor molecules occupy one active site. The binding constant of adsorption $K = k'^{1/y}$, where 1/y is the number of the active surface sites occupied by one molecule of the inhibitor, and k' is the binding constant. Fig. 6 indicates linear relationship between log $\Theta / 1$ - Θ and log C at different temperatures, and the calculated values of 1/y and K are given in Tables 6 and 7.

The free energy of adsorption (ΔG_{ads}) at different concentrations of the natural products as calculated from the following equation:

$$\Delta G_{ads} = -RTLn(55.5 \text{ K}) \tag{11}$$

Where the value 55.5 is the molar concentration of water in the solution mol/1.

The values of ΔG_{ads} are given in Table 7 and negative values in all cases means that spontaneous adsorption of inhibitor on steel surface and strong interaction between the inhibitor molecules and metal surface. The (ΔG_{ads}) values are negative and lie in the range of (32–38) kJmol⁻¹ for Flory - Huggins and (15–17) KJ mol⁻¹ for kinetic isotherm. It's found that (ΔG_{ads}) values are more positive than -40 Kjmol⁻¹ indicating that the inhibitors are physically adsorbed on the metal surface. The results have also been reported by J. D. Talati. [39]

Fig. 5. Flory-Huggins adsorption isotherm at 298 k for different amines.

3.4. Effect of temperature

The temperature effect on the Fe anodic corrosion rate in absence and presence of amines was determined in the temperature range between (25 °C–40 °C). It was observed that the anodic corrosion rate increased with raise in temperature for the different concentrations of amine. The values of E_a that have been calculated from the slopes of Arrhenius plots [40,41]

$$\log I = \log A - E_a / 2.303 R T$$
(12)

where I is the limiting current, A is apre-exponential factor, R is the universal gas constant and T is the absolute temperature.

Figures (7, 8, 9,10, 11,12) represent the relation between ln I and 1/ T for blank solution and for different concentrations of Amines (methyl amine, dimethyl amine, diethyl amine, triethyl amine, diethyl amine, triethanol amine respectively), this Figure shows straight lines and the value of E_a have been derived from slopes of Arrhenius plots and are giving in Table 8. It is obviously seen that E_a values in absence and presence of the Hibiscus extract are less than 40 k.J.mol⁻¹ indicating that the anodic corrosion reaction is under a diffusion control [42].

3.4.1. Thermodynamic treatment of the results

From the integrated form of Arrhenius equation:

$$\ln I = -E_a / RT + \ln A \tag{13}$$

Fig. 6. The Kinetic Thermodynamic isotherm at 298 k for different amines.

where: I is the rate cefficient (rate constant), R is the gas constant (8.314 kJ. mol⁻¹), E_a is the activation energy (kJ.mol⁻¹) and A is the frequency factor. It can be seen that the gradient is given by $-E_a/R$ and intercept by lnA. Table 8 gives the values of E_a for the natural products used. The values of enthalpy ΔH^* , entropy ΔS^* , and free energy (ΔG^*) can be obtained by the equations:

$$\Delta H^* = E_a - RT \tag{14}$$

$$\Delta S^* / R = \ln (k T_e / h)$$
(15)

Fig. 7. The relation between the natural logarithm of the limiting current and 1/T for methyl amine at different concentrations (**mol.l**⁻¹).

$$\Delta G^* = \Delta H^* - T \Delta S^*$$
(16)

where k is Boltzmann's constant, $e=2.7183,\,h$ is Plank's constant, T is absolute temperature and R is the universal gas constant. Adsorption is usually followed by liberation of heat of adsorption, so that $E_a<0,\,$ consequently, the rate of adsorption decreases with raise in temperature and as a result, the surface coverage, $\Theta,$ at given concentration decreases with increasing temperature. It is known that an increase in the heat of adsorption leads to an increase in the energy of adsorption. However rising of temperature acts in the reverse direction, increasing the kinetic energy of molecules, facilitating disruption (consequently in the physical adsorption).

Table 8 shows that the entropy ΔS^* posses high negative values are indicating highly ordered natural products in the solution under investigation. These values found to be independent on the type of natural Products.

Variation in the rate within a reaction series may be caused by changes in either, or both, the enthalpy or the entropy. The correlation between ΔH^* and ΔS^* is a linear relationship may which could be stated algebraically as (Fig. 8)

$$\Delta H^* = \beta \Delta S^* + \text{constant}$$
(17)

$$\delta \Delta H^* = \beta \Delta S^* \tag{18}$$

The operator, δ , concerns difference between any two reactions in series. Substituting from the Eq. (11) into the familiar relationship:

$$\delta \Delta H^* = \delta \Delta G^* + T \delta \Delta S^*$$
⁽¹⁹⁾

We obtain

$$\beta \,\delta \,\Delta \,S^* = \delta \,\Delta \,G^* + T \,\delta \,\Delta \,S^* \tag{20}$$

It follows that when $\delta \Delta G^* = \text{zero}$, then $\beta = T$. In other words, the slope in a linear plot of δH^* versus ΔS^* is the temperature at which all reactions that conform to the line occur at the same rate. β is therefore known as the isokinetic temperature. The isokinetic plot of ΔH^* and ΔS^* for different concentrations of the natural products under study. Fig. 9 and Table 8 was found to be linear and the isokinetic temperature (β) was computed from the slope of the plot as 353 K using divided cell. These values are much higher than that of the experimental temperature 298 K, indicating that the rate of the reaction is enthalpy controlled (40), (41).

Table 8

thermodynamic parameters for (a) methyl amine, (b) dimethyl amine, (c) diethyl amine, (d) triethyl amine, (e) diethanol amine and (f) triethanol amine.

3.5. Structure effect of organic additives

Many additives are known to be capable of adsorption on the anodic substrate, it also can trap in the corrosion over potential. This is due to either the need for electron transfer to occur through the adsorption layer or to form a complex at the electrode surface. A complication of

Fig. 11. The relation between the natural logarithm of the limiting current and 1/T for diethanol amine at different concentrations (**.mol.l**⁻¹).

Blank

Fig. 13. STM (Scanning Electronic Microscopy) of polished steel metal in absence of organic amine compounds.

the metal cation in the solution is also proposed. In many cases, the use of additives is still done in empirical way. Indeed, there are very large numbers of both organic and non-organic substance that can be used. Moreover, their action could be different in function of the substrate, the ion to reduce and the electrolytic condition. For example, re-orientation of the additives on the electrode surface has been observed depending on the surface coverage or pH.

In case of steel, and because of its industrial interest a numbers of researcher have already been undertaken. A complex in solution between amines derivatives and Fe^{2+} cation is formed as a result of transport of steel ions from the interface to the bulk and the work for the discharge of steel complex ion increase.

The study of the effect of nitrogen free amines compounds, on the corrosion process is illustrated by adsorption curves. The efficiency of inhibition decreases in the order: triethanol amine > diethanol amine > triethyl amine > diethyl amine > dimethyl amine > methyl amine.

In acidic medium, N- atom tends to be protonated from acid at the anode steel surface. The above behavior may also be able to discuss on the basis that, triethanol amine and diethanol amine are more inhibitors because the ethanol group is nucleophilic group would lead to more convenient electron density on N-atom. This might led to more convenient electron transfer from functional group to metal anode with subsequent coordination, leading to greater adsorption and inhibition efficiency (Figs. 10–12).

3.6. Scanning electronic microscopy measurements (SEM)

Effect of adding organic additives on the scanning electronic microscopy has been studied. All experiments were carried out at the limiting current determined at 293 K and time of 5 min. Fig. 13 shows the morphology of polished steel metal in absence of organic amine compounds as blank, It can be noticed that under the corrosion layer the initial structure of the unexposed materials can be observed and some holes constituted by accumulation of several cabbage. While, Figs. 14–19 show the morphology of polished steel metal in presence of different organic amine compounds in 8 M H₂SO₄ at the limiting current determined at 293 K and time of 5 min in different concentrations of amine compounds (1 \times 10 $^{-5}$, 50 \times 10 $^{-5}$ mole $l^{\text{-1}}$). These figures show that the presence of some holes constituted of several cabbage, the number of holes decreases in the order of triethanol amine > diethanol amine > diethyl amine > Triethyl amine > dimethyl amine > methyl amine. On the other hand a highly surface roughness appear and some cracks appear which decrease by increasing concentrations from $1 \times 10-5 \text{ mol/l}$ to $50 \times 10-5 \text{ mol/l}$

4. Conclusions

The following conclusions arise from the work described here in:

- 1 A typical polarogram is obtained in this study for triethanol amine in case of divided and undivided cell. The curve is divided into three parts: in the first part, the current density (c.d) is proportional to the voltage. At the second part of the curve, the metal undergoes electro-polishing. In the first part, etching takes place and in the last part, some localized pitting occurs
- 2 The observed limiting current, which represents the rate of Steel metal anodic corrosion in phosphoric acid at different temperature, are found that, the limiting current decrease with increasing the concentration of organic amines.
- 3 The inhibition percent that caused by organic amines range from 5% to 59.9% depending on amine type and its concentration.
- 4 The inhibition efficiency of homologous series of organic substances, differ only in the heteroatom, is usually in the following sequence: $P\,>\,Se\,>\,S\,>\,N\,>\,O$
- 5 The values of ΔG_{ads} are given in negative values in all cases means

Cpd I 1 $(1x10^{-5} \text{ mole } l^{-1}).$ Cpd I 2(50x10⁻⁵ mole l⁻¹). Fig. 14. STM (Scanning Electronic Microscopy) of polished steel metal in presence of methyl amine compounds.

that spontaneous adsorption of inhibitor on steel surface and strong interaction between the inhibitor molecules and metal surface. It lies in the range of (32–38) kJmol⁻¹ for Flory - Huggins and (15–17) KJ mol⁻¹ for kinetic isotherm. It's found that (ΔG_{ads}) values are more positive than -40 Kjmol⁻¹ indicating that the inhibitors are

physically adsorbed on the metal surface.

- 6 It was observed that the anodic corrosion rate increased with raise in temperature for the different concentrations of amine.
- 7 It is obviously seen that E_a values in absence and presence of the Hibiscus extract are less than 40 k.J.mol⁻¹ indicating that the anodic corrosion reaction is under a diffusion control
- 8 The efficiency in inhibition decreases in the order: triethanol amine > diethanol amine > triethyl amine > diethyl amine > diethyl amine > dimethyl amine > methyl amine.
